The Dreispitz is sundial and compass in one. We can determine the time and direction on the loop. This compass works well. It works with a north compass needle. The north compass needle has a fixed offset from the legal time. The legal time is against the legal longitude. The longitude difference is the angle between the indicated longitude and the longitude of observation. The angle is multiplied by 4 to yield the minutes that have to be added to the time shown by the Dreispitz.

The lines that cross the hat show the orbit of the shadow for the indicated date. On the hat show the orbit of the shadow for the direction by turning the indicated latitude onto the correct calendar line. In other places, its top falls find this direction by other line. In other places, one must the marks on the calendar line, taking the time is read off of the hour loops that corresponds to the date.

The variation of solar time against the legal time is already accounted for in the loop. The time that is read off the sundial has a fixed offset when the longitude differs from the indicated one. The difference in eastern longitude between the indicated one and that of the place of observation must be multiplied by 4 to yield the minutes that have to be added to the time shown by the Dreispitz.

To fold it flat:
